Abstract

We present a new Ginzburg-Landau theory for superconductivity in UPt_3 , based upon a multicomponent order parameter transforming under an irreducible space group representation; the phase is staggered in real space. Our model can explain the $H - T - P$ phase diagram including the tetracritical point for all field directions. We motivate this unconventional superconducting state in terms of odd-in-time-reversal pairing that may arise in one- or two-channel Kondo models, and suggest experimental tests.

PACS numbers: 74.20.De, 74.70.Tx, 74.25.Dw, 64.60.Kw

Heavy fermion superconductors have continued to attract attention since their discovery in 1979 [1]. In these materials, fermionic excitations with effective masses hundreds of times the free electron mass undergo a pairing transition. Anomalous power laws in low temperature thermodynamic and transport properties [1] together with complex phase diagrams suggest interpretation in terms of Cooper pairs with exotic symmetries. For example in the magnetic field-temperature $H - T$ plane for ambient pressure $P \approx 1$ bar, the hexagonal material UPt_3 apparently possesses three distinct superconducting phases, shown as A, B, C in Fig. 1 [2]. In the $P - T$ plane for zero H there are similarly three observed phases [3]. Intriguingly, the B phase in UPt_3 appears to break time reversal symmetry $\mathcal{T}$ in that muon spin rotation spectroscopy reveals the development of tiny additional magnetic

moments (order $0.001\mu_B$) [4]. So far, no comprehensive microscopic theory exists for these materials and so much theoretical effort has been devoted to phenomenological approaches. No such approach to date has successfully explained UPt_3 without substantial fine tuning of parameters.

In this Letter, we propose a new model for the phase diagram of UPt_3 in which finite center of mass momentum (FCM) pairs give rise to an order parameter which transforms as a triplet under the operations of the full hexagonal space group. Our model produces a plausible description of the $H-P-T$ superconducting phase diagram. In particular, we can explain the tetracritical point found for all field orientations. While the Ginzburg-Landau free energy contains numerous parameters, experiment constrains the zero field values to a narrow region which allows for a $\mathcal{T}$ -breaking B phase. The crystalline structure of UPt_3 plays a crucial role in our considerations. The proposed superconducting order parameters are microscopically motivated in terms of odd-in- $\mathcal{T}$ pairing [5] such as may arise in the two-channel Kondo model [6,7] suggested for heavy fermion materials [8]. Such pairs may generically give rise to negative pair hopping energy favoring staggered superconducting states [9]. We shall discuss data supporting this odd-in- $\mathcal{T}$ pairing and point out crucial tests of our model as well as some of its limitations. We note that our theory is applicable only near T_c and H_{c2} , and is macroscopic in character. Explanation of the low temperature power laws awaits the development of a suitable microscopic approach.

To place our work in context, we first discuss the E doublet model [10]. In this picture, the Cooper pairs have zero center of mass momentum (ZCM), and are described by basis functions $\phi_a(\vec{k}), \phi_b(\vec{k})$ which form a closed vector space under the symmetry operations of the hexagonal space group. With each basis function is associated an order parameter amplitude $\eta_{a,b}$, defined through the gap function $\Delta(\vec{k}) \sim \eta_a \phi_a(\vec{k}) + \eta_b \phi_b(\vec{k})$. The phenomenological approach consists of writing down and minimizing a Ginzburg-Landau free energy which is an expansion in the η amplitudes. A zero field splitting is present which most likely originates in the orthorhombic strain induced by magnetic order. Then the three phases have $\eta_a \neq 0, \eta_b = 0$ (A -phase), $\eta_a \neq 0, \eta_b \neq 0$ (B -phase), $\eta_a = 0, \eta_b \neq 0$ (C -phase). The apparent

time reversal breaking in the B -phase is explained by suitable a choice of Ginzburg-Landau parameters which energetically favor a relative phase factor of i between η_a, η_b . The E model has a flaw: while the data show a tetracritical point for all field orientations, a tetracritical point generically arises only for in-plane magnetic fields [11]. This problem is remedied by fine tuning to zero the gradient term in the free energy which mixes the a, b components [10]. As a possible alternative, the authors of Ref. [11] propose a model of accidentally nearly degenerate ZCM singlet states (DS model) which have no such gradient mixing term. While this can explain the tetracritical point for all field orientations, there is no compelling explanation for the accidental near degeneracy.

Our work proceeds via a different phenomenological route: by considering Cooper pairs with FCM, we are free to examine space group representations which merge the desirable properties of the E doublet and DS models by having order parameter degeneracy and the absence of gradient mixing terms enforced by symmetry.

Before turning to the core of the paper, we shall briefly review the motivation for this work in terms of odd-in- $\mathcal{T}$ pairing theory. For an odd in $\mathcal{T}$ pair wave function it may be shown within a quasiparticle framework [5,9] that (i) for ZCM pairs, the “Meissner stiffness” which goes as $1/\lambda_L(T)^2$, λ_L the London penetration depth, is *negative*; (ii) an immediate corollary is that the pair transfer energy between two odd-in- $\mathcal{T}$ slabs, or Josephson coupling, is negative—alternatively, the coefficients of the gradient terms in the free energy are negative. To the extent that these properties are generically true (it is unknown whether a quasiparticle picture is applicable in all cases), we then expect a non-uniform superconducting state in which the pairs have FCM and the phase is modulated in real space. Indeed, the Majorana Fermion treatment of the ordinary Kondo lattice model favors just such a state, with the superconducting order parameter fully staggered, i.e., the pair hopping from site to site is negative [9].

There is so far no numerical evidence supporting this odd-in- $\mathcal{T}$ picture for the single channel Kondo lattice model [12]. There are strong reasons to consider this state in the two-channel Kondo lattice model. In this model, two identical “channels” of spin 1/2 conduction

electrons interact antiferromagnetically with a lattice of spin 1/2 local moments. For this model it has been shown that (i) in the impurity limit, the pair field susceptibility for the odd-in- $\mathcal{T}$ order parameter which is a singlet in spin and channel indices diverges as $-\ln(T)$, $T \rightarrow 0$, and (ii) all heavy fermion superconductors have appropriate symmetry and dynamical conditions to be describable by two-channel Kondo models [8,13]. For the uranium based materials a two-channel quadrupolar Kondo model can apply, with spin corresponding to local quadrupolar indices and the channel labels corresponding to conduction magnetic indices. The spin and channel singlet states transform as the A_2 representation for each point group relevant to the heavy fermion materials [14] ($A_2 \sim (x^3 - 3xy^2)(y^3 - 3yx^2)$ for the hexagonal point group).

Assuming that such local odd-in- $\mathcal{T}$ pairs of A_2 point symmetry form at each site with negative pair hopping in the heavy fermion superconductors, we can determine the allowed multidimensional space group representations which describe the ordering in each compound. Note that such a description is reasonable only to the extent that the Kondo screening length is strongly reduced in the lattice relative to the impurity, which is in fact expected in the single channel Kondo lattice model [15]. In a hexagonal crystal with one 4f/5f atom per unit cell the pair energy minima will be at the two K points of Fig. 2. For UPt_3 , the crystal structure with two atoms per unit cell and interlayer frustration for antiferromagnetic (phase) couplings pushes the pair hopping minima away from the K points, and for a wide range of parameter values they move to the M points which have a three point star [16]. In addition, the presence of two atoms per unit cell gives rise to non-degenerate bonding and non-bonding combinations of pair orbitals within each cell. We assume that the non-bonding combination is sufficiently high in energy to be negligible in the current analysis.

We now turn to the discussion of a specific Ginzburg-Landau model for UPt_3 based upon the 3 dimensional M -point representation. While motivated by the odd-in- $\mathcal{T}$ order parameter discussion above, we are not limited to this as a potential microscopic source for our phenomenology. Free energy invariants are constructed by standard group theoretical methods, and we have checked the completeness of our set using image group techniques [17].

We include a linear coupling to an orthorhombic strain field ϵ , which breaks the hexagonal symmetry. The free energy density is given by

$$F = F_0 + F_g^{ab} + F_g^c \quad (1a)$$

$$F_0 = \alpha_+ |\eta_3|^2 + \alpha_- (|\eta_1|^2 + |\eta_2|^2) + \beta_1 \sum_n |\eta_n|^4 + \beta_2 \sum_{n \neq m} |\eta_n|^2 |\eta_m|^2 + \beta_3 \sum_{n \neq m} \eta_n^2 \eta_m^{*2} \quad (1b)$$

$$F_g^{ab} = \sum_n \{ \mu_n (|p_+ \eta_n|^2 + |p_- \eta_n|^2) + \mu'_n (|p_+ \eta_n|^2 - |p_- \eta_n|^2) + (\nu_n (p_+ \eta_n)(p_- \eta_n)^* + c.c.) \} \quad (1c)$$

$$F_g^c = \sum_n \chi_n |p_z \eta_n|^2 \quad (1d)$$

Here, η_n , $n=1,2,3$, are the order parameter components, $p_{\pm} = (p_x \pm ip_y)/\sqrt{2}$, $p_{\alpha} = -i\partial_{\alpha} - 2eA_{\alpha}/\hbar c$ ($e < 0$), and $\alpha_{\pm} = a_0(T - T_{\pm})$ with $T_+ = T_{c0} + 2\epsilon/a_0$ and $T_- = T_{c0} - \epsilon/a_0$. For the odd-in- $\mathcal{T}$ order parameter considered in the frequency domain, the η_i are understood to be the leading order coefficients of the expansion about $\omega = 0$ [5]. We will restrict further analysis to the case $\epsilon > 0$ ($T_+ > T_-$), which is a necessary condition to comply with the suggested $\mathcal{T}$ -breaking in phase B but not in phase A. The coefficients of the gradient terms are expanded to linear order in ϵ and are defined by a number of phenomenological coupling constants κ_j through $\mu_n = \kappa_1 + \kappa_2 \epsilon \text{Re}(\gamma^n)$, $\mu'_n = \kappa_3 \epsilon \text{Im}(\gamma^n)$, $\nu_n = \kappa_4 \gamma^n + \kappa_5 \epsilon + \kappa_6 \epsilon \gamma^{-n}$, and $\chi_n = \kappa_7 + \kappa_8 \epsilon \text{Re}(\gamma^n)$. The phase factor $\gamma = \exp(i2\pi/3)$ reflects the three-fold symmetry of the star of M. Note that the last term in Eq. (1b) favors $\mathcal{T}$ -breaking solutions for $\beta_3 > 0$.

Model (1) accounts for a rich phase diagram already when $H = 0$. Fig. 3 summarizes the stability region of zero field solutions. Four regions in the parameter space can be distinguished according to their predicted phase sequence, as shown in Table 1 [20]. Most promising with regard to experiment are regions I and II. Both allow for two second order transitions at T_+ and $T_*(< T_+)$, where the second phase manifestly breaks $\mathcal{T}$ -symmetry and can be identified with phase B of Fig. 1b.

For region I, we recover the experimental $P - T$ diagram, when we assume a pressure dependent strain field, which decreases with increasing P and vanishes for $P > P_c$ [21]. On

the other hand, a third low-temperature phase for finite ϵ is predicted for region II, which signals an unlocking of the relative phases of the order parameter components. Consequently, a fourth superconducting phase D appears between B and C , and all phase boundaries meet at a pentacritical point. Although this scenario seems to be at variance with Fig. 1b, we cannot immediately reject it because the BD and DC boundaries are predicted to be very close together rendering an observation of the fourth phase difficult. Estimates for the model parameters, as derived from experimental data (shaded area inside the region of stability in Fig. 3) do not unambiguously favor one of the two regions.

Let us now discuss the $H - T$ diagram predicted by model (1). Generally, the upper critical field H_{c2} is determined by the smallest eigenvalue of the linearized Ginzburg-Landau equations [11,22], which can be seen as a coupled system of Schrödinger-like equations, with the order parameter playing the role of a multicomponent wavefunction. In our case, this leads to three *decoupled* equations, which makes it possible to obtain all eigenvalues in a closed analytic form for a general magnetic field. For $\mathbf{H} = H(\cos \varphi \sin \theta, \sin \varphi \sin \theta, \cos \theta)$, H_{c2} is given by the largest of the three values

$$H_n(T) = \frac{\hbar c}{2|e|} \frac{-\alpha_n(T)}{\sqrt{R_n} + \mu'_n \cos \theta}$$

$$R_n = (\mu_n^2 - |\nu_n|^2) \cos^2 \theta + \chi_n(\mu_n - Re(\nu_n e^{i2\varphi})) \sin^2 \theta \quad (2)$$

where $\alpha_3 \equiv \alpha_+$ and $\alpha_1 = \alpha_2 \equiv \alpha_-$.

A tetracritical point in the $H - T$ plane corresponds to a crossing of the two largest values H_n as a function of temperature. As mentioned by Garg [22], such a crossing necessarily requires the existence of a conserved quantity associated with the Schrödinger equations. For our model, this property follows immediately from the decoupling of the equations dictated by translational invariance, therefore allowing, in principle, a tetracritical point for *all* directions of the magnetic field. Within a one domain model, the almost complete isotropy of H_{c2} in the basal plane [23] requires that the in-plane anisotropic gradient terms are very small ($|\nu_n| \ll \mu_n$). For the extreme case $\nu_n = 0$, we find kinks in H_{c2} for all field directions provided that $\kappa_1 > 0$, $\kappa_7 > 0$, $\kappa_2 + |\kappa_3|/\sqrt{3} > 0$, and $\kappa_2\kappa_7 + \kappa_1\kappa_8 > 0$ [24]. These

constraints do not represent strong limitations. Note, that the gradient terms proportional to ϵ are necessary for a tetracritical point to appear because for vanishing strain the slopes of the H_n versus T lines would be identical. As a consequence, the slopes of the low-field and high-field H_{c2} -lines (AN and CN phase boundaries in Fig. 1a) approach the same value for $\epsilon \rightarrow 0$, i.e. for $P \rightarrow P_c$. This holds for any field direction, and represents a qualitative difference from the predictions of the E model, where the slope difference approaches a nonzero limit for in-plane fields and vanishes for c-axis fields.

Our model is further consistent with observed anisotropies of the penetration depth and H_{c1} , and predicts a kink of H_{c1} at T_* for all field directions because of an onset of an additional order parameter component below T_* .

The above given analysis of the phase diagram assumes a homogeneous symmetry breaking field. This one-domain picture is an oversimplification of the situation in UPt_3 . Any orthorhombic field is very likely to build a six-fold domain structure, as it was observed for the antiferromagnetic order with domain sizes of less than 150 Å. Such an underlying domain structure can significantly alter the superconducting state [25]. This point deserves further investigation to allow a more reliable comparison with experiment.

Our model may resolve some additional phenomenological puzzles. Most notable is the absence of Josephson tunneling from conventional superconductors into heavy fermion materials, in particular for UPt_3 [26]. Assuming the superconductivity to arise from FCM pairs with odd-in- $\mathcal{T}$ symmetry, no single pair Josephson coupling to a conventional even-in- $\mathcal{T}$ superconductor is possible without applied or internal (spontaneous) magnetic field that breaks $\mathcal{T}$. Even in this case the staggered phase across an arbitrary sample face will yield zero net pair tunneling unless: (i) one cleaves along planes perpendicular to the pairing k -vectors, or (ii) one uses atomic scale tunneling probes (e.g., STM), which can sample a small region of non-zero phase. This suggests a clear experimental test of the odd-in- $\mathcal{T}$ hypothesis.
